

Internship proposal
2nd semester of Master 2
2022-2023

Team: Biophotonics of molecular and cellular interactions

Unit: Laboratory of Bioimaging and Pathologies (LBP) UMR 7021

Address: Faculty of Pharmacy, 74 route du Rhin Illkirch

Team's website: <https://lbp.unistra.fr/en/umr-7021/research-teams/biophotonics-of-the-molecular-and-cellular-interactions>

Doctoral School: Life Sciences ED 414

Fluorescence tools to characterize Liquid-Liquid Phase Separation

Liquid-liquid phase separation (LLPS) is a thermodynamically driven phenomenon during which a homogeneous solution de-mixes to form two separate liquid phases. One appears as dense droplet like structures dispersed in a second more diluted phase. During the last decade, LLPS has emerged as a fundamental phenomenon driving the assembly of intracellular biomolecular condensates also called membrane-less organelles (MLOs, e.g. nucleolus, Cajal bodies P bodies, stress granules). MLOs represent multicomponent system that displays droplet-like properties such as ability to flow and coalesce. Due to their transient and dynamic nature, these organelles play major roles in gene regulation and signaling pathways or serve as storage compartments making the biological material immediately available. Hence, MLOs internal environment is optimally tuned to ensure efficient biochemical reactions together with an optimal exchange rate with its external environment. Consequently, the deregulation of LLPS process is associated with pathologies including cancer, neurodegenerative and infectious diseases. At present, the biophysical understanding of LLPS, as a process orchestrating the MLOs assembly and internal organization, is only emerging and the experimental tools used to characterize the LLPS in vitro and in cellulo are limited.

The aim of the internship is (i) to characterize the biophysical properties of model droplets with the help of environmentally sensitive dyes (solvatochromic probes and molecular rotors) and (ii) to monitor the phase separation properties of the nucleolus in living cells. By tuning the experimental conditions (temperature, concentration, pH, ...), model systems will be first used to correlate the optical properties of the dyes to physicochemical properties (hydration, local viscosity) of model condensates. Their optical properties will be monitored by means of steady state and time resolved spectroscopy together with phase contrast and fluorescence microscopy. Based on the calibration performed with in vitro model systems, quantitative fluorescence imaging will be used to measure directly in cells the polarity and the viscosity within nucleolus in physiological and under stress conditions. Such ambitious experiments will allow us to monitor the biophysical properties of condensates with improved spatial and temporal resolutions.

Required skills: the candidate must display a strong motivation for experimental work at the interface between physics and chemistry. Knowledge in fluorescence microscopy would be appreciated.
